# Oberon Data Types 

Matteo Corti<br>corti@inf.ethz.ch

December 5, 2001

## 1 Introduction

This document is aimed at students without any previous programming experience. We briefly describe some data types of the Oberon language and how they are internally represented.

This document is distributed in the hope that it will be useful, but without any warranty; Without even the implied warranty of merchantability or fitness for a particular purpose.

## 2 Definitions

Bit A bit (binary digit) is the smallest unit of information the computer uses. It can assume only two values 1 or 0 .

Byte A byte is a group of 8 bits, strung together.

## 3 Numbering systems

The decimal numbering system represents numbers using ten different symbols (digits from 0 to 9 ) in a positional system: The meaning of a symbol is also determined its position. A digit $d$ at the $n^{\text {th }}$ position from right to left starting at 0 , has a value of $d \cdot 10^{n}$.

Similarly other numbering systems with different sets of digits can be used.
The binary system uses only two digits 0 and 1 , which are called bits. The value of a bit at the $n^{\text {th }}$ position is $b \cdot 2^{n}$.

The hexadecimal system uses 16 symbols (digits from 0 to 9 and letters from A to $\mathrm{F}^{1}$ ). The value of an hexadecimal digit at the $n^{\text {th }}$ position is $h \cdot 16^{n}$.

The following examples show some convertions between different number systems:

$$
\begin{aligned}
2001 & =2 \cdot 10^{3}+0 \cdot 10^{2}+0 \cdot 10^{2}+1 \cdot 10^{0} \\
& =2000+0+0+1 \\
& =2001
\end{aligned}
$$

[^0]\[

$$
\begin{aligned}
01010110 & =0 \cdot 2^{7}+1 \cdot 2^{6}+0 \cdot 2^{5}+1 \cdot 2^{4}+0 \cdot 2^{3}+1 \cdot 2^{2}+1 \cdot 2^{1}+0 \cdot 2^{0} \\
& =0+64+0+16+0+4+2+0 \\
& =88 \\
3 F 4 C & =3 \cdot 16^{3}+F \cdot 16^{2}+4 \cdot 16^{1}+C \cdot 16^{0} \\
& =3 \cdot 16^{3}+15 \cdot 16^{2}+4 \cdot 16^{1}+12 \cdot 16^{0} \\
& =12288+3840+64+12 \\
& =16204
\end{aligned}
$$
\]

The hexadecimal numbers are widely used in computer science, because they can be easily converted from and to binary once: Each hexadecimal digit corresponds exactly to four bits. An example is depicted in the following table:

| binary | 0011 | 1111 | 0100 | 1100 |
| :---: | :---: | :---: | :---: | :---: |
| decimal | 3 | 15 | 4 | 12 |
| hexadecimal | 3 | F | 4 | C |

### 3.1 Negative numbers

With $n$ bits you can represent $2^{n}$ different numbers, for example integers between 0 and $2^{n}-1$. The problem arises when we want to express negative numbers, as we have to choose an appropriate representation.

A trivial method uses the first bit to express the minus sign, but we have the problem that two different representations for 0 are possible (with 8 bits 00000000 will be 0 and 10000000 will be -0 which is nonsensical).

Negative numbers are usually represented by the so called 2's complement notation. To obtain the 2 's complement of a number, first take the complement (invert each bit) and then add 1. All the negative numbers will have a 1 in the most significant bit ${ }^{2}$ position (MSB), and the numbers will now range from $-2^{n-1}$ to $2^{n-1}-1$.

For example, if we want to express -42 in a 8 bit system we first convert 42 to binary obtaining $00101010(0 \cdot 128+0 \cdot 64+1 \cdot 32+0 \cdot 16+1 \cdot 8+0 \cdot 4+1 \cdot 2+0 \cdot 1)$. We then compute the complement 11010101 and we finally add 1 obtaining 11010110.

### 3.2 Floating-point

Floating-points numbers approximate real $(\mathbb{R})$ numbers. A floating-point number $r$ is represented by a signed mantissa $m$ and a signed exponent $n$ with respect to a base b:

$$
r= \pm m \cdot b^{ \pm n}
$$

The IEEE standard for single-precision floating point format allocates 1 bit for the sign of the number, 8 bits for the signed exponent and 23 bits for the mantissa.

[^1]
### 3.3 Numbers in Oberon

Integer numbers in the decimal notation are expressed as usual with a sequence of digits that can be preceded by a minus sign:
integer := digit \{digit\}.
Hexadecimal numbers are expressed with a capital H at the end:
integer := digit \{hexDigit\} "H".
Note that the first digit of an hexadecimal number cannot be a letter, numbers beginning with a letter must be preceded by a 0 (e.g. 0AFH).

## 4 ASCII

Numbers are also used to represent characters. The standard way to do this is the American Standard Code for Information Interchange or ASCII (pronounced "Ask-ee"). ASCII is a 7-bit code, thus allowing to code $128\left(2^{7}\right)$ different symbols.

| Oct | Dec | Hex | Char | Oct | Dec | Hex | Char |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 000 | 0 | 00 | NUL '\0' | 100 | 64 | 40 | @ |
| 001 | 1 | 01 | SOH | 101 | 65 | 41 | A |

| 077 | 63 | 3 F | $?$ | 177 | 127 | 7 F | DEL |

The extended ASCII code (8 bits) can represent an additional set 128 characters which are not part of the standard and are platform and and configuration specific (this means that german letters as ä, $\ddot{u}$ and $\ddot{\text { ö are not part of the standard }}$ ASCII code).

## 5 Oberon data types

Oberon offers eight different basic data types: BOOLEAN, CHAR, SHORTINT, INTEGER, LONGINT, REAL, LONGREAL and SET.

### 5.1 BOOLEAN

BOOLEAN can express only two different values: TRUE or FALSE. Although a boolean can be expressed with one bit only, for practical reasons one or more bytes are commonly used.

### 5.2 CHAR

Character constants are expressed with the corresponding symbol or with the index in the ASCII table in hexadecimal form followed by a capital X (e.g. "o" or 06FX).

```
CharConstant = """ character """ | digit {hexDigit} "X".
```

CHAR can express the extended ASCII set (from 000X to 0FFX).

### 5.3 SHORTINT, INTEGER and LONGINT

Integer types represent signed integer values between MIN(type) and MAX(type). On 32 bits CPUs this normally means:

| Type | Size | MIN(type) | MAX(type) |
| :--- | ---: | ---: | ---: |
| SHORTINT | 8 bit | -128 | 127 |
| INTEGER | 16 bit | -32678 | 32677 |
| LONGINT | 32 bit | 2147483648 | -2147483647 |

### 5.4 REAL and LONGREAL

REAL and LONGREAL express real numbers between MIN(type) and MAX(type).
On 32 bits CPUs the IEEE single and double precision floating point format is usually used ( 32 and 64 bits).

### 5.5 SET

A SET represents the set of integers between 0 and MAX(SET). On 32 bits CPUs MAX(SET) is normally 31 .

### 5.6 Order

Numeric types form a hierarchy; the larger type can represent (the values of) the smaller type:
$\mathrm{LONGREAL} \subseteq \mathrm{REAL} \subseteq \mathrm{LONGINT} \subseteq \mathrm{INTEGER} \subseteq \mathrm{SHORTINT}$

### 5.7 Conversions

A value of a smaller type is converted in a larger type implicitly, as shown in the following example:

```
PROCEDURE Foo();
VAR
    s: SHORTINT;
```

```
    i: INTEGER;
    l: LONGINT;
BEGIN
    i := s;
    l := s;
    l := i
END Foo;
```

Other explicit conversions are possible as shown in the following table

| Name | Argument type | Result type | Function |
| :--- | :--- | :--- | :--- |
| ORD $(\mathrm{x})$ | CHAR | INTEGER | ordinal number of x |
| CHR(x) | integer type | CHAR | character with ordinal number x |
| SHORT $(\mathrm{x})$ | LONGINT <br> INTEGER <br> LONGREAL | INTEGER <br> SHORTINT <br> REAL | identity (truncation possible) |
|  | INTEGER <br> SHORTINT <br> REAL | LONGINT <br> INTEGER <br> LONGREAL | identity |
|  | real type | LONGINT | largest integer not greater than x <br> Note that ENTIER(i/j) $=\mathrm{i}$ DIV j |

Particular attention must be paid to explicit convertions since the smaller type is not always able to hold the converted value as in the following example:

```
PROCEDURE Foo();
VAR
    s: SHORT;
    i: INTEGER;
BEGIN
    i := 300; (* i = 000000100101100 or 300 *)
    s := SHORT(i) (* s = 0101100 or 44 *)
END Foo;
```

[^0]:    ${ }^{1}$ Letters from A to F have a value of 10 to 15 in the decimal system, e.g. D has a value of 13.

[^1]:    ${ }^{2}$ The MSB or most significant bit is the bit with the most significat position, in our case the leftmost bit
